ABSTRACT

Power system components are exposed to transient oscillation of voltage and current produced by energizing and de-energizing devices. These transients may be short lived, but they have high peak values and frequency much greater than power system fundamental frequency. The factors that influence their intensities is shown. Characteristics of the transient resulting from the switching utility capacitor bank is analysed in the paper with simulation.

Keywords: Capacitor Switching, Inrush Current, Natural Frequency, Transient, Harmonics.

I. INTRODUCTION

The application of capacitor banks has long back accepted as a necessary step in the efficient design of power systems for power factor improvement, losses reduction, voltage control, or released capacity [5]. Capacitor switching is just one of the many switching events that can cause transients in the system. However due to their regularity and impact on power system equipment, they often receive special consideration. Transient overvoltage and overcurrent related to capacitor switching are classified by peak magnitude, frequency and duration. These parameters are useful for evaluating potential impact of these transients on power system equipment [2]. Switching large capacitors on the three-phase system is source of several problems. The voltage disturbance associated with current transient that occur at the instant of switching are the most severe problem. If this transient are not limited then amplitude of these transients can easily exceed than normal current and their duration can last up to several milliseconds [3]. These transients can cause voltage dips and tripping of power electronic based devices. Also due to their extreme amplitude, these transient can cause premature wear of mechanical contact and shorten capacitor life.

II. BASIC CONCEPTS CONCERNING ENERGIZATION OF CAPACITORS

Switching of the capacitor bank is a delicate operation due to the nature of such particular network component. In the basic characteristic of capacitor is that the voltage cannot change instantaneously; in other words, closing on a capacitor bank is almost like closing on a short circuit initially. Therefore, when capacitor is connected to power network voltage will pull down to nearly zero for certain time interval. A high current peak, namely an inrush current, will occur while the capacitor is charging. At the same movement the capacitor voltage will start
to recover from its initial state and overshoot the system voltage. The capacitor voltage then oscillate around the network voltage for few cycles. As in the case of switching where a second capacitor bank is connected in parallel to one already connected bank (back to back switching), the charged bank dumps a high frequency current peak into the uncharged capacitor bank. The inrush current resulting from back to back closing is much higher in magnitude and frequency compared to single bank closing.

The primary frequency of the oscillation is generally in the range 300- 1000 Hz, although higher frequency component result from the initial step change. Damping from system resistance and loading determines how long the disturbance lasts, typically between 0.25 and 0.5 cycles. The transient magnitude for normal energizing are generally in the range of 1.1 to 1.5 per unit. The higher transients are associated with larger capacitors and weaker system.

There are several different type capacitor bank transient such as normal switching, back to back switching, magnification transients and restrike transients. Back to back energizing occurs when there is a capacitor already energized close to the capacitor switched. The transient frequency in the current is relatively high due to the inrush current from the energized bank to the one being energized, i.e. more than 1000 Hz. The higher frequency oscillation dies out quickly and then there is a lower frequency oscillations determined by the combination of parallel capacitor with the system source inductance. Magnification of capacitor switching transient occurs when a resonance with smaller low voltage capacitor bank.th overvoltage transients in the customer facility can exceed 2.0 per unit and disrupt equipment operation. The frequency of the magnification transients is typically less than that of a normal energizing. De-energizing a capacitor bank should not produce any noticeable transients. However, an unsuccessful de-energization can produce significant transients due to restrike during a failed capacitor opening. When initial contact opening is not successful, an arc forms between the contact and re-energizes bank. This type of energizing is not desire and is consider an abnormal switching. The transient characteristics in restrike energizing are essentially identical with normal energizing, expect that that the step change at the energizing instant is much higher and severe for restrike energization. When capacitor bank opens, there are trapped charges in the bank and when restrike occur the system voltage might be opposite polarity causing the step change to go pass zero.

III. A PARAMETERIC STUDY

3.1 Inrush current

Inrush current (input surge current or switch–on surge) refers to the maximum, instantaneous current drawn by an electrical device when first turned on. The inrush current into the newly connected bank is determine by the size of the bank and inductance between two banks. The larger the banks, and the smaller the inductance between banks, the higher will be inrush current. The frequency of the inrush current is determine by the ratio of capacitor bank reactance and the impedance between the banks. The smaller the impedance, the higher will be the frequency.as per the standards(IEC 62305-1-2012,IEC 600060-1-2010, and IEC 62475-1-2010),the inrush
current characterized by following parameters; peak magnitude(kA), maximum time rate of change(kA/s), time of first peak, frequency, time integral of absolute value of inrush current, Energy(kJ).

3.2 Harmonics

Apart from power, electronics devices there are other sources of harmonic distortion such as arcing devices and equipment with saturable ferromagnetic core. Application of capacitor bank can create series or parallel resonance problem, which magnifies the problem of distortion. Due to harmonics there is increase in the RMS value of current it causes excessive heating in system components. IEEE standard 519-1992 recommends limits for the both utility and customers.

IV. CAPACITOR ENERGIZATION

Mathematical relation for nature of inrush current and voltage as follows.

Fig.1 Parameters of capacitor being switched in
Total inductance for the circuit = L_s + L_tr = L
The total resistance for the circuit = R + R_tr = R
Capacitance = C
Main frequency = F_1 = \omega_1 / 2\pi
Specific frequency = F_2 = \omega_2 / 2\pi
V_1 = voltage at the fundamental frequency across the capacitor (peak value)
I_1 = fundamental frequency load current (peak value)
\Phi = phase angle differencen technique V_1 and I_1
i_1 = value of I_1 at instant t
V_e = supply voltage at specific frequency across the capacitor (peak value)
I_e = supply current at specific frequency across the capacitor (peak value)
\gamma = phase angle difference between V_e and I_e
i_e = value of I_e at instant t
i_1 + i_e = total current at any instant t

\[ i_t = I_1 \cos (\omega_1 t + \Phi) + I_e \cos (\omega_2 t + \gamma) e^{\frac{-t}{\tau}} \]  (1)

\[ V_1 + V_e = \text{total voltage across the capacitor at instant t} \]

\[ V_1 + V_e = I_1 \cos (\omega_1 t + \Phi) + I_e \sqrt{\frac{1}{C}} e^{\frac{-t}{\tau}} \sin (\omega_2 t + r - \delta) \]  (2)
When there is load across the line, the load resistance is very small and $\delta = 0$. The bornitz gives the following relationships:

\[ I_e = -I_1 \left[ \cos^2 \Phi + \left( \frac{\omega_2}{\omega_1} \right)^2 \sin^2 \Phi \right]^{\frac{1}{2}} \]  
\[ V_e = -V_1 \left[ \left( \frac{\omega_2}{\omega_1} \right)^2 \cos^2 \Phi + \sin^2 \Phi \right]^{\frac{1}{2}} \]  

From this we get points:

4.1 A capacitor bank with a large KVAR has large capacitance $C$ resulting in a small $X_C$. On the distribution lines, short circuit capacities are low. $X_L$ is high. A small value capacitor (low $C$ and thus high $X_C$) is switched across high short circuit capacity (low $X_L$) line. Then high ratio of $\omega_2/\omega_1$, high specific frequency. Result in sparking and explosion of capacitor.

4.2 A high specific frequency $\omega_2$ means sharper rates of rise of current and voltage. This leads to sparking during switching. A lower specific frequency should not be so low that is coincides with the lower harmonics of the main frequency and result in the resonance.

4.2.1 When load increases a new capacitor bank joins as existing capacitor bank. Both are switched through a common switch. Total $C$ increases and $X_C$ decreases. This result $\omega_2/\omega_1$ and hence no sparking.

4.2.2 It is advisable to increase $X_L$ by series inductor in series with a capacitor bank always on the HV and EHV circuit at the location closed to power generating station. This lower $\omega_2/\omega_1$ and reduces the danger. Standard percentage inductances are KVAR are 6% and 0.2% of the capacitor KVAR.

4.2.3 Phase angle of load has an influence on the peak magnitude of surge current.

\[ I_e = -I_1 (\cos^2 \Phi + (\omega_2/\omega_1)^2 \sin^2 \Phi)^{1/2} \]  

$\Phi = 0$ That is, power factor almost unity. Then $I_e = -I_1$  

$\Phi = 90$ that is load is almost inductive with practically no power component. $I_e = -I_1 (\omega_2/\omega_1)$

4.3 Effect of load on the surge current:

4.3.1 When there is no load, the step down transformer on the other side or the open lines have $\Phi$ of $90^\circ$, giving the high possible value of $I_e$, so there may be flash over while testing capacitor under no load condition.

4.3.2 As the load increases, the power factor towards unity. It also absorbs the more and more of the surge energy being in parallel across the capacitor. The surge is rapidly damped down. Thus switching large capacitor bank of appropriate sizes when there is justified load is fairly safe.

4.4 Influence of the switching instant:

4.4.1 Switching instant when the voltage passes through zero.

The sum of both stationary values and the exponential oscillatory values of the voltage and current naturally zero, since there is no voltage in the system. For both the system, the voltage and current will be $90^\circ$ phase difference, with current leading the voltage wave. System1 will oscillate at the frequency 50 Hz steady voltage and current. System2 will oscillate at the specific frequency $\omega_2$ at decreasing values of the voltage and current. Thus under conditions of zero voltage crossing $I_1 = -I_e$ since they cancel out at start. Both are peak values since
\( V_e \) is zero. As per the equation. This implies \( \Phi = 0 \). This gives \( V_e = V_1 e^{i \omega_1 t} \) as the maximum possible value. Since the \( \omega_2 > \omega_1 \), \( V_e < V_1 \) and dies down quickly. The maximum instantaneous current will be less than \( 2I_1 \) and the maximum instantaneous capacitor voltage will not exceed \( V_1(1 + \frac{\omega_1}{\omega_2}) \). Both these condition are favourable for the operation of a capacitor and its switching devices.

4.4.2 Switching in at the instant when the voltage is at its peak value:
At the instant of peak voltage, the mains capacitor current, which is 90\(^\circ\) out of phase will be zero. The instantaneous current will also start with a zero but will rise to its peak value within a quarter cycle of its specific frequency, which is normal quite high.

The peak value of the instantaneous current is given by \( I_e = -V_1 \sqrt{\frac{C}{L}} \) since the voltage is common to both the systems.

\[
\begin{align*}
\text{(5)} \quad I_e &= -V_1 \sqrt{\frac{C}{L}} \\
\text{(6)} \quad I_e &= -I_1 \sqrt{\frac{1}{1+\frac{\omega_1}{\omega_2} C}} \\
\text{(7)} \quad I_e &= -I_1 \sqrt{\frac{XC}{XL}}
\end{align*}
\]

V. PARALLEL SWITCHING OF A CAPACITORS:
When an additional capacitor bank \( C_2 \) is switched on across a bus where an existing capacitor bank \( C_1 \) is already energized, the bank \( C_2 \) has surge current drawn from two sources, the main and the already energized bank \( C_1 \).

Fig.2 Parallel switching of capacitor bank
Under the worst possible conditions, switching can take place when the main frequency voltage is passing through its peak. We will consider the two instantaneous current for \( C_2 \) separately.

The current drawn by \( C_2 \) from the mains will be
\[
I_{c1} = -V_{c1} \sqrt{\frac{C_1}{L_{\text{mains}}}} \quad \text{(8)}
\]

The current drawn by \( C_1 \), which now is a source of supply will be given by
\[
I_{c2} = -V_{c1} \sqrt{\frac{C_2}{L_{\text{bus}}}} \quad \text{Where} \quad C = \frac{C_1 C_2}{C_1 + C_2} \quad \text{(9)}
\]

These two current will have separate specific frequencies. However, these current will add up \( I_{c2} \) become very large, since the inductance of the bus system between the two capacitors is almost negligible.
VI. SIMULATION DETAILS

The MATLAB SIMULINK (2015b) software is used to simulate the circuit and to measure the inrush current and voltage.

VII. RESULTS
VIII. CONCLUSION

In this paper characteristics of transients, which originated from capacitor bank switching were studied. Moreover, the factors that influence the intensity of such transients were investigated in order to identify the condition in which these effects can be determined. The MATLAB/SIMULINK is used to simulate the inrush current in back to back switching of capacitor bank.
